December 2016

Abstract

In this study, interactions between potential hierarchical value chains existing in the production structure and industry-wise productivity growths are sought. We applied generalized Chenery-Watanabe heuristics for matrix linearity maximization to triangulate the input-output incidence matrix for both Japan and the Republic of Korea, finding the potential directed flow of values spanning the industrial sectors of the basic (disaggregated) industry classifications for both countries. Sector specific productivity growths were measured by way of the Trönqvist index, using the 2000-2005 linked input-output tables for both Japan and Korea.

Abstract

In this study, interactions between potential hierarchical value chains existing in the production structure and industry-wise productivity growths are sought. We applied generalized Chenery–Watanabe heuristics for matrix linearity maximization to triangulate the input–output incidence matrix for both Japan and the Republic of Korea, finding the potential directed flow of values spanning the industrial sectors of the basic (disaggregated) industry classifications for both countries. Sector specific productivity growths were measured by way of the Trönqvist index, using the 2000–2005 linked input–output tables for both Japan and Korea.

Keywords: Triangulation, Linked Input–Output Tables, Linear Ordering Problem, Productivity Growth

1. Introduction

The structure of production, as defined by the input–output table, is the result of the interaction of a variety of forces that are prevalent in an economy. While there are variations in the relative scarcity of factors of production and differences in levels of income and final demand, we may expect similarity in the structure of production, to the extent that production is based on the same body of technological knowledge and constrained by the same physical laws. The structure of production has been investigated as to whether there is a significant relation between the degree of development and the hierarchy of industrial value chains, based on the triangulation of input–output tables. The pioneering study by Chenery and Watanabe (1958) indicated that the production structures of more developed countries are similar to certain extent. Simpson and Tsukui (1965) have argued the existence of a fundamental structure of production common to modern economic systems. In the same vein, Korte and Oberhofer (1971), Lamel et al. (1972), Song (1977), Fukui (1986), Östblom (1993), Kondo (2014) are also concerned with the similarities and stabilities of the structure of production in different economies.

The analysis of the industrial hierarchy leading from primary to final commodities forms a basis for comparison of economy-wide production structures. Such an inter-industrial value chain of activities is studied by triangulating input–output transactions. An input–output table records the flow of outputs from each industrial sector into each factor input of sectors as a factor-by-industry matrix. One may find an appropriate order for factor inputs and industry outputs that herds the entries into the upper-diagonal. If the inter-industrial transaction of industrial activities were

Figure 1: Production structure and the input–output configuration

perfectly hierarchical, such as that shown in Figure 1 (left), the input–output table can be established as an upper-diagonal matrix, such as that shown in Figure 1 (right). If, on the other hand, there are circular flows of commodities, we will not be able to observe such a perfect triangular system of production.

The degree to which an economic structure agrees with a triangular hierarchy of the industries is called *linearity*. Linearity of a matrix is the ratio of the sum of the elements above the diagonal to the sum of all elements except the diagonal. Naturally, the linearity of a perfectly triangular matrix is unity. Hence, the input–output table triangulation problem is to find the hierarchical order (sequence) of industries (and the corresponding commodities) that maximizes the linearity of the input–output table. This is also known as the linear ordering problem. Previous researchers have observed that large and highly developed economies tend to have a low degree of linearity whereas underdeveloped economies tend to exhibit a clearer linearity. According to Leontief (1986) typical linearity is around 70% for a developed economy and 90% for an underdeveloped economy.

A linear ordering problem is usually associated with an immense feasible region, as the ordering involves permutations. Such a combinatorial optimization problem is known to be NP-hard; one has to assess the linearity of $n!$ permutations of n industries which can get quite large. Naturally, exact methodologies using ring shift permutation (Haltia, 1992; Östblom, 1993) or mixed integer programming (Kondo, 2014) for solving linear ordering problems have limitations in terms of the dimension of the matrix that can be handled. On the other hand, heuristic methods (such as tabu search, simulated annealing, genetic algorithms, evolution strategies, etc.) have shown to be able to efficiently find quality solutions in many combinatorial problems. One of the earliest efficient heuristics for the linear ordering problem was the one proposed by Chenery and Watanabe (1958). This heuristic method orders the industrial sector in a hierarchy according to the ratio of total factor inputs to the total intermediate output. Due to its simplicity, this method is applicable to large-scale linear ordering problems.

In this project, as we are concerned with triangulating input–output tables of the order of 400 industrial sectors, we naturally take the heuristic approach. More specifically, we generalize the heuristic method of hierarchical ordering of Chenery and Watanabe (1958) by differentiating the assessment of industry-wise ratios of total inputs and outputs. Our empirical study will be focused on a production structure comparison between Korea and Japan. Moreover, we will be comparing the triangulated ordering of the industrial sectors along with the total factor productivity growth, in

terms of the sector-wise Trönqvist indexes, for the two countries. In so doing, we use the 2000–2005 linked input–output tables for both Japan (MIAC, 2011) and Korea (BOK, 2015). The dimensions of these tables are 395 and 350 sector-by-commodity transactions for Japan and Korea, respectively. These linked input–output tables include factor-wise deflators (price indices) for input factors. For primary factors, i.e., labor and capital, the quality adjusted deflators were compiled by JIP (2015) for Japan and KIP (2015) for Korea.

The remainder of this paper is organized as follows. In the next section, we introduce the basics of matrix triangulation and productivity growth estimation using linked input–output transaction tables. In Section 3, we apply the protocol introduced in the previous section using the data observed for 2000–2005 in Japan and Korea, and discuss the observed correlations between the hierarchical order of sectors and the sector-wise productivity changes. Section 4 provides concluding remarks.

2. The Analytical Framework

2.1. Production Structure

The analysis of the hierarchy of sectors from the primary factor leading to final outputs forms a basis for the analysis of macroscopic production structures. Triangulation of the input–output transaction matrix is a standard method of arranging sectors into hierarchical order, such as processing sequences of intermediate commodities from upstream to downstream. The circular interdependences present in the macroscopic production, however, do not allow one to observe a perfect triangular structure of production as illustrated in Figure 1. The degree to which a macroscopic production structure agrees with a hierarchical order of processing sequences is called linearity.

In a perfectly linear structure, the processing sequences will cascade from upstream to downstream sectors but never the opposite; and in that case, we may arrange the rows and columns of the input–output matrix according to the hierarchical order to obtain an upper-triangular matrix (with all entries at and below the diagonal being zero). More specifically, for an n -sector output system with $n - 1$ intermediate inputs (excluding self-input), the most upstream sector has no intermediate input with $n - 1$ output destinations (i.e., zero column and $n - 1$ row entries) whereas the most downstream sector has $n - 1$ inputs with no intermediate output destination (i.e., $n - 1$ column and zero row entries).¹

Let us denote an order of n industrial sectors, whose initial order is $(1, 2, \dots, n)$, by a permutation mapping $\pi : (\pi(1), \pi(2), \dots, \pi(n))$. Further, we let $k(\pi) = \{k' \mid k = \pi(k')\}$, so that we may write a π permuted version of a matrix $\mathbf{M} = \{m_{ij}\}$ as

$$\mathbf{M}(\pi) = \{m(\pi)_{ij}\} = \{m_{i(\pi)j(\pi)}\}$$

For later discussion let us work on a discretized square input–output matrix \mathbf{M} , where we call it an input–output incidence matrix, whose element is binary i.e., $m_{ij} = 1$ if transaction $x_{ij} \neq 0$, and

¹Note that, the primary input (the 0th input), which is essential in all production but is not produced by any of the n sectors, will be placed at the ultimate upstream position.

$m_{ij} = 0$ if $x_{ij} = 0$. The linearity ℓ of \mathbf{M} under permutation π is defined as follows:

$$\ell = \frac{\sum_{i < j} m(\pi)_{ij}}{\sum_{i \neq j} m(\pi)_{ij}} = \frac{h(\mathbf{M}(\pi))}{K}$$

Note that the denominator K , is a constant representing the sum of all the entries in the matrix, except for the diagonal entries. The numerator $h(\mathbf{M}(\pi))$, on the other hand, is dependent on the permutation.

The triangulation problem of a matrix \mathbf{M} is to find a permutation mapping that maximizes the linearity, that is to

$$\max_{\pi \in \Pi} \ell = h(\mathbf{M}(\pi)) / K$$

where, Π is the set of all possible permutations. This problem is also known as the linear ordering problem (see, e.g., Chaovalitwongse et al., 2011). Note that, for an $n \times n$ matrix, the number of possible permutations would be as large as $n!$. This can get quite large, and the problem is known to be NP-hard. Presumably, none of the exact methods (typically, by way of discrete optimization) will work when one attempts to handle a matrix of 395 sectors, as $395!$ is a huge number. Thus, we take a heuristic approach.

For that matter one may use the ratio of the input incidences total (column sum of \mathbf{M}) to the output incidences total (row sum of \mathbf{M}), which we denote by r_1 and arrange the permutation in the descending order of this ratio.² More specifically the ratio is defined as follows:

$$\ln r_1(k) = \ln \sum_{j=1}^n m_{kj} - \ln \sum_{i=1}^n m_{ik} \quad k = 1, 2, \dots, n$$

This heuristic method is a simple example of the approach proposed by Chenery and Watanabe (1958), except that the original study uses the input–output coefficient matrix. Note that in this case the set of possible permutations contains only one element, which we denote by π_1 ; that is, $\Pi = \{\pi_1\}$. In other words, permutation $\pi_1 : (\pi_1(1), \pi_1(2), \dots, \pi_1(n))$ is the descending order of the above mentioned ratios $r_1 : (r_1(1), r_1(2), \dots, r_1(n))$, or, $r_1(1(\pi_1)) \geq r_1(2(\pi_1)) \geq \dots \geq r_1(n(\pi_1))$.

In this study we slightly generalize this Chenery–Watanabe heuristic approach. In particular, we take the *weighted* ratio of the input incidences total to the output incidences total, as described below, in order to expand the number of possible permutations Π .

$$\ln r_\gamma(k) = \ln \sum_{j=1}^n m_{kj} - \gamma \ln \sum_{i=1}^n m_{ik} \quad k = 1, 2, \dots, n$$

Obviously, this ratio includes the Chenery–Watanabe case by setting $\gamma = 1$. Accordingly, we evaluate the linearity of \mathbf{M} with a permutation $\pi_\gamma : (\pi_\gamma(1), \pi_\gamma(2), \dots, \pi_\gamma(n))$ with respect to the

²In other words, sector k with large $r_1(k)$ is placed upstream of sectors with a smaller value.

descending order of the ratios $r_\gamma : (r_\gamma(1), r_\gamma(2), \dots, r_\gamma(n))$, such that $r_\gamma(1(\pi_\gamma)) \geq r_\gamma(2(\pi_\gamma)) \geq \dots \geq r_\gamma(n(\pi_\gamma))$ for any $\gamma \in \Gamma$, where Γ is a set of allowable values for the weighting γ . Note that, γ must be nonnegative, according to the purpose of triangulation of matrix \mathbf{M} . Obviously enough, $\gamma \in [0, 1)$ if we are to put more weight on the outputs, and $\gamma \in (1, \infty)$ if we are to put more weight on the inputs. Our objective would hence be to search for the policy on γ that maximizes the linearity, that is to

$$\max_{\gamma \in \Gamma} \ell = h(\mathbf{M}(\pi_\gamma)) / K \quad (1)$$

Hereafter we call the order π_{γ^*} that maximizes the ℓ of (1) the flow order.

2.2. Productivity Growth

Below we describe the production function of an industrial sector. (Note that we omit the industrial sector-wise index j .)

$$y = zF(x_0, x_1, \dots, x_n) \quad (2)$$

where, y is the output of production, x_i is the i th factor input, and z is the (total factor) productivity or the TFP. TFP represents the level of technology of the industry. The main production function F is assumed to be homogeneous of degree one (or, constant returns to scale) reflecting perfect competition among the many firms within the industry.

By taking logarithms and time derivatives we obtain

$$\frac{\dot{y}}{y} = \frac{\dot{z}}{z} + \left(\frac{\partial F}{\partial x_0} \frac{x_0}{F} \right) \frac{\dot{x}_0}{x_0} + \left(\frac{\partial F}{\partial x_1} \frac{x_1}{F} \right) \frac{\dot{x}_1}{x_1} + \dots + \left(\frac{\partial F}{\partial x_n} \frac{x_n}{F} \right) \frac{\dot{x}_n}{x_n} \quad (3)$$

As we assume perfect competition, the marginal rate of technical substitution (MRTS) must equal the price ratio: that is,

$$\text{MRTS} = \frac{\partial zF}{\partial x_i} = \frac{w_i}{c} \quad (4)$$

Note that w_i and c denote the i th factor price and the unit output cost which equals the price, respectively. Using (4) we can show that the parts of (3) in parentheses equal the cost share, which we denote by a_i :

$$\frac{\partial F}{\partial x_i} \frac{x_i}{F} = \frac{\partial zF}{\partial x_i} \frac{x_i}{zF} = \frac{w_i}{c} \frac{x_i}{y} = a_i \quad (5)$$

Alternatively, we may work on the following unit cost function that is compatible with the production function (2):

$$c = z^{-1} H(w_0, w_1, \dots, w_n) \quad (6)$$

By taking logarithms and time derivatives we obtain

$$\frac{\dot{c}}{c} = -\frac{\dot{z}}{z} + \left(\frac{\partial H}{\partial w_0} \frac{w_0}{H} \right) \frac{\dot{w}_0}{w_0} + \left(\frac{\partial H}{\partial w_1} \frac{w_1}{H} \right) \frac{\dot{w}_1}{w_1} + \dots + \left(\frac{\partial H}{\partial w_n} \frac{w_n}{H} \right) \frac{\dot{w}_n}{w_n} \quad (7)$$

As we assume perfect competition we apply Shepherd's Lemma to (6) then we have

$$\frac{\partial z^{-1} H}{\partial w_i} = \frac{x_i}{y} \quad (8)$$

Using (8) we can show that the parts of (7) in parentheses equal the cost share:

$$\frac{\partial H}{\partial w_i} \frac{w_i}{H} = \frac{\partial z^{-1} H}{\partial w_i} \frac{w_i}{z^{-1} H} = \frac{x_i w_i}{y c} = a_i \quad (9)$$

Now, the productivity growth, i.e., $\Delta \ln z$ where Δ indicates the difference between the two periods, can be found by integrating (3) or (7) over two periods $t = 0, 1$:

$$\Delta \ln z = \int_0^1 d \ln z = \int_0^1 d \ln y - \sum_{i=0}^n \int_0^1 a_i d \ln x_i = -\int_0^1 d \ln c + \sum_{i=0}^n \int_0^1 a_i d \ln w_i$$

Note, however, that the integrations can be evaluated only if we know the time trajectory of a_i . Nonetheless, if we can approximate the time variate a_i with a constant such as

$$a_i = \frac{a_i^0 + a_i^1}{2}$$

where the superscripts indicate the equilibrium states (0 for reference, 1 for current states), the productivity growth can be evaluated by

$$\Delta \ln z = \Delta \ln y - \sum_{i=0}^n \frac{a_i^0 + a_i^1}{2} \Delta \ln x_i = -\Delta \ln c + \sum_{i=0}^n \frac{a_i^0 + a_i^1}{2} \Delta \ln w_i \quad (10)$$

The measurement of the relative productivity change, i.e., $\exp(\Delta \ln z) = z^1/z^0$, via (10) is known as the Törnqvist index. Diewert (1976) showed its exactness in measuring the productivity growth of Translog functions. Thus, we know that (10) is equal to the productivity growth of the underlying Translog function with or without knowledge of its parameters. Star and Hall (1976) showed that the Törnqvist index is a good approximation of productivity growth measurement irrespective of the type of aggregator function and the interval of observations. For practical purposes, we measure productivity growth in terms of the Törnqvist index, which we denote by TFPg, using the formula

$$\text{TFPg} = -\ln p + \sum_{i=0}^n \left(\frac{a_i^0 + a_i^1}{2} \right) \ln p_i \quad (11)$$

where, p_i denotes the current (factor) price relative to the reference state, or the deflator, such that

$$p_i = \exp(\Delta \ln w_i) = w_i^1/w_i^0$$

3. Empirical Analysis

3.1. The Data

A set of linked input–output tables includes sectoral transactions in both nominal and real terms. The 1995–2000–2005 linked input–output tables for both Japan (MIAC, 2011) and Korea (BOK, 2015) include factor-wise deflators spanning the fiscal years recorded in the tables. A deflator is a price index that standardizes the nominal value of a commodity at the target state into a real value relative to the reference state. The above mentioned linked input–output tables include 395 factor-by-sector and 350 factor-by-sector transaction tables for Japan and Korea, respectively, along with the corresponding factor-wise deflators, for three five-year periods. These tables, however, do not include deflators for primary factors (i.e., labor and capital) and, therefore, we used the quality-adjusted price indexes compiled by JIP (2015) for Japan and by KIP (2015) for Korea in order to inflate the primary inputs observed in nominal values. In this study, we use input–output transactions for the year 2000 as the reference state and that of 2005 as the current state.

3.2. Results and Discussion

In Figures 2 and 3, we show the results of searches for an optimal γ for Japan and Korea, respectively, where we used the domain $\Gamma = [0, 3]$ in (1). The maximizing policy was $\gamma^* = 1.61$ for Japan, and $\gamma^* = 1.47$ for Korea, where the maximized linearities were $\ell(\gamma^*) = 0.83$ for Japan and $\ell(\gamma^*) = 0.74$ for Korea. Note that the linearities of the original sector classification order based on Colin Clark’s three-sector theory were very close: $\ell(\text{original}) = 0.43$ for Japan and $\ell(\text{original}) = 0.43$ for Korea. Also note that the *densities* of the input–output incidence matrix, that is, $\sum_{ij} m_{ij}/n^2$, were 0.274 for Japan and 0.297 for Korea. Figures 4 and 5 show the triangulation of the input–output incidence matrix of the original order (left) to that of the triangulated flow order (right) for Japan and Korea, respectively.

The productivity growths (TFPg) obtained using (11) for all industrial sectors are summarized in Table 2 and 3 (Appendix) for Japan and Korea, respectively. Note that the industrial sectors are sorted by the flow order (upstream to downstream) according to the maximized linearity. In Figures 6 and 7 we display TFPg against the flow order of industrial sectors for Japan and Korea, respectively. The average TFPg, $\sum_j \text{TFPg}_j/n$, was -0.0052 for Japan and -0.0399 for Korea. The variances of TFPg, as is apparent from the figures, are different: the standard deviation for Japan was 0.115 whereas that for Korea was 0.204. Any correlation between TFPg and flow order was hardly observable, however.

Hence, we looked into the quadrant classification for industrial sectors, referring to Chenery and Watanabe (1958), using two dimensions, namely, the incidence sums of inputs and outputs. More specifically, we first classified the industrial sectors into two groups, according to the sector-wise number of outputs (row sum of the incidence matrix): the upper half (with many output incidences) is called *Manufacturing* whereas the lower half is called *Primary*. Next, we classified each group, (*Manufacturing* and *Primary*), into two groups, according to the sector-wise number

Table 1: Quadrant classification of Industrial Sectors

	Final Inputs with lower $\sum_j m_{ij}$	Intermediate Inputs with higher $\sum_j m_{ij}$
Manufacturing Outputs with higher $\sum_i m_{ij}$	III Final Manufacture Made from Many Used by Few 26% of all sectors (JPN) 20% of all sectors (KOR) TFPg (average) = -0.0062 (JPN) TFPg (average) = -0.0670 (KOR)	II Intermediate Manufacture Made from Many Used by Many 24% of all sectors (JPN) 30% of all sectors (KOR) TFPg (average) = -0.0197 (JPN) TFPg (average) = -0.0610 (KOR)
Primary Outputs with lower $\sum_i m_{ij}$	IV Final Primary Made from Few Used by Few 24% of all sectors (JPN) 30% of all sectors (KOR) TFPg (average) = -0.0069 (JPN) TFPg (average) = -0.0150 (KOR)	I Intermediate Primary Made from Few Used by Many 26% of all sectors (JPN) 20% of all sectors (KOR) TFPg (average) = -0.0020 (JPN) TFPg (average) = -0.0200 (KOR)

of inputs (column sum of the incidence matrix); the upper half (with many input incidences) is called *Intermediate* whereas the lower half is called *Final*. The quadrant classifications of sectors are hence called (I) *Intermediate Primary*, (II) *Intermediate Manufacture*, (III) *Final Manufacture*, and (VI) *Final Primary*. The quadrant classification is summarized in Table 1. Note that the upper stream sector corresponds to category I, the lower stream sector corresponds to category III.

In Japan 26% of all sectors (103 out of 395) were categorized as I and III, and 24% (95 out of 395) were categorized as II and IV. In Korea, 20% of all sectors (70 out of 350) were categorized as I and III, and 30% (105 out of 350) were categorized as II and IV. The average TFPg values for categories I, II, III, and IV, were -0.0020 , -0.0197 , -0.0062 , -0.0069 , respectively; in other words, sectors in category I (Intermediate Primary) had the largest productivity growth, and those in category II (Intermediate Manufacture) had the least productivity growth, whereas the sectors in the Final categories (III and IV) had moderate growth in Japan. In contrast, the average TFPg values for categories I, II, III, and IV, were -0.0200 , -0.0610 , -0.0670 , -0.0150 , respectively in Korea; in other words, sectors in the Primary categories (I and IV) gained more productivity than the sectors in the Manufacturing categories (II and III). Figures 8 and 9 illustrate TFPg with respect to the quadrant classification for the two countries. Also, in Tables 2 and 3 the column sum and the row sum of the input–output incidence matrix are displayed as “Column” and “Row”, respectively. The corresponding segment Category is also attached.

4. Concluding Remarks

Indubitably, productive improvement in upstream industry, rather than in the downstream industry, has a greater impact on a highly integrated production economy. Thus, in this study, we looked into correlations between the hierarchical value chain that exists in the production structure, and industry-wise productivity growths. We applied generalized Chenery–Watanabe heuristics for matrix linearity maximization, in order to triangulate the input–output incidence matrix for both Japan and Korea, thus finding the directed flow of values of input–output transactions among the industrial sectors in both countries.

In this study we have found larger variance in productivity growth among industrial sectors for Korea than for Japan, while the productivity growths were, on average, much the same. As regards the directed flow of values, the correlations between productivity growths were rather equivocal. However, as we aggregate the hierarchical order of industrial sectors by way of quadrant classification, we have found that the Intermediate Primary (i.e., upstream) segment had improved more, in terms of productivity, relative to other segments, in both countries. On the other hand, rather counter-intuitively, the Intermediate Manufacture segment had less improvement in terms of productivity in both countries.
